ABSTRACT
Micro emulsions are clear, stable, isotropic mixtures of oil, water and surfactant, frequently in combination with a co-surfactant. Micro emulsions act as potential drug carrier systems for oral, topical, and parenteral administration. They offer the advantage of spontaneous formation, ease of manufacturing and scale-up, thermodynamic stability, and improved drug solubilization and bioavailability. Knowledge of the various methods available to thoroughly characterize a microemulsion system is essential. While microemulsion is used in several fields, in this review the pharmaceutical applications are emphasized. Micro emulsions are one of the best candidates as novel drug delivery system because of their long shelf life, improved drug solubilization with ease of preparation and administration. They have emerged as novel vehicles for drug delivery which allow controlled or sustained release for ocular, percutaneous, topical, transdermal, and parenteral administration of medicaments. The main objective of this review paper is to discuss Micro emulsions as drug carrier system with other possible applications.

Key words: Microemulsion, Oil, Water, Vehicle, Surfactant, Drug Delivery.

INTRODUCTION
The pharmaceutical term “emulsion” is most time used to indicate preparations prepared for internal use. Emulsions for external use are always given a different title that it focus may indicate their use, e.g. lotion and cream (Christopher and Dawn, 2008). An emulsion may be defined as a biphasic system consisting of two immiscible liquids, one of which (the dispersed phase) is finely and uniformly dispersed as globules throughout the second phase (the continuous phase). Micro emulsions are clear, stable, isotropic liquid mixtures of oil, water and surfactant, frequently in combination with a co-surfactant. The aqueous phase may contain salt(s) and/or other ingredients, and the “oil” may actually be a complex mixture of different hydrocarbons and olefins. In contrast to ordinary emulsions, micro emulsions form upon simple mixing of the components and do not require the high shear conditions generally used in the formation of ordinary emulsions. The two basic types of micro emulsions are direct (oil dispersed in water, o/w) and reversed (water dispersed in oil, w/o) 1-3. In principle, micro emulsions can be used to deliver drugs to the patients via several routes, but the topical application of micro emulsions has gained increasing interest. The three main factors determining the transdermal permeation of drugs are the mobility of drug in the vehicle, release of drug from the vehicle, and permeation of drug into the skin. These factors affect either the thermodynamic activity that drives the drug into the skin or the permeability of drug in the skin, particularly stratum corneum. Micro emulsions improve the transdermal delivery of several drugs over the conventional topical preparations such as emulsions and gels 4-7. Mobility of drugs in micro emulsions is more facile 8, as compared to the micro emulsion with gel former which will increase its viscosity and further decrease the permeation in the skin 8. The superior transdermal flux from micro emulsions has been shown to be mainly due to their high solubilization potential for lipophilic and hydrophilic drugs.

TYPES OF EMULSION

OIL IN WATER EMULSION
If the oil droplets are dispersed throughout the aqueous phase, the emulsion is termed oil-in-water (0/W) as shown in Fig1. Fats or oils for oral administration, either as medicaments in their own right, or as vehicles for oil soluble drugs, are always formulated as oil in water (0/W) emulsions (Aulton, 1996). They are non greasy and are easily removable from the skin surface and they are used externally to provide cooling effect and internally to also mask the bitter taste of oil. Water soluble drugs are more quickly released from O/W emulsion.

Fig.1: 0/W emulsion.

WATER IN OIL EMULSION
A system in which the water is dispersed as globules in the oil continuous phase is termed water-in-oil emulsion (W/O) as shown in Fig.2. Water-in-oil emulsions will have an occlusive effect by hydrating the stratum corneum and inhibiting evaporation of eccrine secretions. It has an effect on the absorption of drugs from W/O emulsions. W/O emulsion is also useful for cleansing the skin of oil soluble dirt, although its greasy texture is not always cosmetically acceptable (Aulton,
Micro emulsions are systems consisting of water, oil and surfactant, which constitute a single optically isotropic and thermodynamically stable liquid solution. A simple way to formulate a micro emulsion was to suggested by Hoar and Schulman. There are two types of micro emulsion, one is O/W and the second is W/O micro emulsion. For preparation of O/W micro emulsion, we start with w/o emulsion using a low hydrophylc- lipophylc balance (HLB) number surfactant. To this emulsion, an aqueous solution of high HLB number surfactant is added while stirring at a certain amount of addition, a 'gel' phase is produced and further addition of surfactant solution, an inversion into O/W emulsion take place. For W/O micro emulsion, one start with O/W emulsion stabilized with an ionic or nonionic surfactant. This emulsion is titrated with a co-surfactant and the emulsion passes through a gel phase, after which further addition of co-surfactant result in the production of W/O micro emulsion. However, a drawback of micro emulsion is the possibility of disruption of the crystalline structure of stratum corneum. These lead to facilitated transdermal transport and skin irritation.

Pickering Emulsion
The solid particles in the colloidal size may be used as emulsion stabilizers. Such particles are known as pickering emulsion. Pickering emulsions are recently employed in many areas like cosmetics, food, pharmaceuticals, oil recovery and waste water treatment.

Basic Differences between Macroemulsion and Microemulsion

Types of Micro Emulsions
Micro emulsions are thermodynamically stable, but are only found under carefully defined conditions. According to Winsor, there are four types of micro emulsion phases exists in equilibria, these phases are also referred as Winsor phases. They are,

1. O/W microemulsion or winsor I
2. W/O microemulsion or winsor II
3. Bicontinuousmicroemulsion or winsor III
4. Single phase homogeneous mixture or winsor IV
5. O/W micro emulsion or winsor I

In Oil-in-water type of micro emulsions droplets of oil is surrounded by a surfactant (and may be co-surfactant) film that forms the internal phase distributed in water, which is the continuous phase. This type of micro emulsion generally has a larger interaction volume than the w/o micro emulsions.

W/O micro Emulsion or Winsor II
In Water-in-oil type of micro emulsions droplets of water surrounded by a continuous oil phase. These are recognized as "reversemicelles", where the polar headgroups of the surfactant are facing into the droplets of water, with the fatty acid tails facing into the oil phase. A w/o micro emulsion used...
Review Article

orally or parenterally may be destabilized by the aqueous biological system.

**BICONTINUOUS MICRO EMULSION OR WINSOR III**

In bicontinuous microemulsion systems the amount of water and oil present are similar. In this case, both water and oil exist as a continuous phase. An irregular channel of oil and water are combined, and looks like a “sponge-phase”. Transitions from o/w to w/o Micro emulsions may pass through this bicontinuous state. Bicontinuous microemulsion, may show non-Newtonian flow and plasticity. These properties make them especially useful for topical delivery of drugs or for intravenous administration.

**SINGLE PHASE HOMOGENEOUS MIXTURE OR WINSOR IV**

In single phase homogeneous mixture or Winsor IV the oil, water and surfactants are homogenously mixed.

**INGREDIENTS OF MICROEMULSION 17-19**

Various ingredients are used in the formulation and development of Micro emulsions. Mainly oil and surfactants are used in microemulsion they should be biocompatible, non-toxic and clinically acceptable. Main components of microemulsion are

1. Oilphase
2. Aqueousphase
3. Surfactant
4. Co-solvent

**OIL PHASE 20**

Oil is one of the most important components of microemulsion because it can solubilize the required dose of the lipophilic drug and it increases the fraction of lipophilic drug transported via the intestinal lymphatic system. The examples of such phase are cyclohexane, mineral oil, toluene, & vegetable oil etc.

**AQUEOUS PHASE**

Generally the aqueous phase contains hydrophilic active ingredients and preservatives. Sometimes Buffer solutions are used as aqueous phase.

**SURFACTANT 21**

The term surfactant (surface-active-agent) denotes a substance which exhibits some interfacial or interfacial activity & used to lower the surface or interface tension. It has affinity for polar & nonpolar solvents. Surfactants are the molecules that contain a polar head group and a polar tail. Surfactant molecules self-associate due to various inter- and intra-molecular forces as well as entropy considerations. The surfactant molecules can arrange themselves in a variety of shapes. They can form spherical micelles, a hexagonal phase, lamellar (sheet) phases, rod shaped micelles, reverse micelles, or hexagonal reverse micelles. At low concentrations of dispersed (internal) phase, spherical, isolated droplets are present in the micro emulsions. The various types of surfactants that help in the progressive development of micro emulsion system are

1. Cationic
2. Anionic
3. Non-ionic
4. Zwitterionic surfactants.

**CATIONIC SURfactant**

Cationic Surfactants when come in contact with water they come into amphiphilic cation and anion form, most often of halogen type. A very large quantity of this class corresponds to nitrogen compounds such as quaternary ammoniums and fatty amine salts, with one or several long chain of the alkyl type, often coming from natural fatty acids. The most well-known examples from the cationic surfactant class are hexadecytrimethyl ammonium bromide and didodecyl ammonium bromide. These surfactants are in general more expensive than anionics.

**ANIONIC SURFACTANT**

When anionic surfactants are dissociated in water in an amphiphilic anion, and a cation, which is in general an alkalin metal (Na,K) or aquatamary ammonium. These are the most commonly used surfactants. The anionic charge in these surfactants comes from the ionized carboxyl group. Anionic surfactants account for about 50 % of the world production. Alkalalkanoates, also known as soaps, are the most common anionic surfactants. This is the most well-known type of surfactant when it comes to their shape and function. The three most important anionic groups in all of these surfactants are carboxylate, sulfonate and sulfategroups.

**NON-IONIC SURFACTANT**

Non-ionic surfactant is stabilized by dipole and hydrogen bond interactions with the hydration layer of water on its hydrophilic surface. They do not ionize in aqueous solution, because their hydrophilic group is of non-dissociable type, such as phenol, alcohol, ester, or amide. A large proportion of these nonionic surfactants are made hydrophilic by the presence of a polyethylene glycolchain.

**ZWITTERIONIC SURFACTANT**

Zwitterionic surfactants contain both positively and negatively charged groups and form micro emulsions by addition of co-surfactants. Phospholipids, such as lecithin, obtained naturally from soybean or egg are common zwitterionic surfactants. Unlike other ionic surfactants, which is somewhat toxic, lecithin which contains diacylphosphatidylcholine as the major constituent show excellent biocompatibility. Other important class of zwitterionic surfactants is the betaines, such as alkylbetaines, and heterocyclic betaines.

**CO-SOLVENT 22**

It has been observed that single-chain surfactants are unable to reduce the o/w interfacial tension sufficiently to form a micro emulsion. The addition of co-surfactants allows the interfacial film to be flexible to take up different curvatures required to form micro emulsion over a wide range of excipients. If a single surfactant film is desired, the lipophilic chains of the surfactant should be sufficiently short, or contain fluidizing groups (e.g. unsaturated bonds). Basic co-surfactants are short chain alcohols (ethanol to butanol), glycols such as propylene glycol, medium chain alcohols, amines or acids. The use of co-surfactant is to destroy liquid crystalline or gel structures that come in place of a micro emulsion phase.

**METHOD OF FORMULATION 23,24**

Micro emulsions are prepared when interfacial tension at the oil/water is kept at very low level. Interfacial layer is kept very much flexible and fluid concentration of surfactants should be high enough to give surfactant molecules to be stabilized the
microemulsion at an extremely low interfacial tension. Two main method are reported for the formulation of microemulsion, these are

1. Phase Inversion Method
2. Phase Titration Method

PHASE INVERSION METHOD

In the phase inversion method phase inversion of Micro emulsions occurs by addition of excess amount of the dispersed phase. During phase inversion quick physical changes occur including changes in particle size that can affect drug release both in vivo and in vitro. For non-ionic surfactants, this can be completed by changing the temperature, forcing a transition from oil in water microemulsion at low temperatures to water in oil microemulsion at higher temperatures (transitional phase inversion). During cooling, the system crosses a point of zero spontaneous curvature and minimal surface tension, promoting the formation of finely dispersed oil droplets. This method is also known as phase inversion temperature (FIT) method. Other than temperature, other parameters such as pH value or salt concentration may be considered more effectively instead of the temperature alone. Additionally, a transition in the spontaneous radius of curvature can be obtained by changing the water volume fraction. By successively adding water into oil, initially water droplets are formed in a continuous oil phase. By increasing the water volume fraction changes the spontaneous curvature of the surfactant from initially stabilizing a w/o micro emulsion to an o/w microemulsion at the inversion point.

PHASE TITRATION METHOD

Micro emulsions are formulated by the spontaneous emulsification method (phase titration method) and can be shown with the help of phase diagrams. A mixture of fatty acid and oil is added to a caustic solution to prepare a microemulsion, then after it is titrated with a co-surfactant, an alcohol, until the system turned clear. Micro emulsions are formed along with various association structures (including emulsion, micelles, lamellar, hexagonal, cubic, and various gels and oily dispersion) depending on the chemical composition and concentration of each component. It is found that as the chain length of the surfactant increased, Micro emulsions with significant transmittances by visible spectrum can be formed with oils of longer chain lengths. It is also found that different alcohols affect the formation of Micro emulsions in different ways. The best results, in terms of the greatest percent transmittance coupled with the widest range of oil (dispersed in water) concentration, are obtained from short or branched alcohols.

FACTOR AFFECTING FORMULATION OF MICRO EMULSION SYSTEM

PROPERTY OF SURFACTANT

Surfactant contains two group lipophilic and hydrophilic groups. Hydrophilic single chain surfactants such as cetyl alcohol ammonium bromide dissociate completely in dilute solution and have a tendency to form o/w microemulsion. When the surfactant is in presence of salt or when high concentration of surfactant is used, degree of dissociation of polar groups becomes lesser and resulting system may be w/o type.

Property of Oil Phase

Oil phase also influence curvature by its ability to penetrate & Swell the tail group region of the surfactant monolayer, swelling of tail results into an increased negative curvature to w/o microemulsion.

PACKING RATIO

HLB of surfactant determines the type of microemulsion through its influence on packing and film curvature. The analysis of film curvature for surfactant association’s leading to the formation of microemulsion.

TEMPERATURE

Temperature is extremely important in determining the effective head group size of nonionic surfactants. At low temperature, they are hydrophilic and form normal o/w system. At higher temperature, they are lipophilic and form w/o systems. At an intermediate temperature, microemulsion coexists with excess water and oil phases and forms bicontinuous structure.

APPLICATION OF MICROEMULSION SYSTEM

MICROEMULSION IN PHARMACEUTICAL

From last two decades there has been a revolution in the utilization of microemulsion systems in a variety of pharmaceuticals.

PARENTERAL DELIVERY

Parenteral administration (especially via the intravenous route) of drugs with limited solubility is a major problem in industry because of the extremely low amount of drug actually delivered to a targeted site. Microemulsion formulations have distinct advantages over macroemulsion systems when delivered parenterally because of the fine particle microemulsion is cleared more slowly than the coarse particle emulsion and, therefore, have a longer residence time in the body.

ORAL DELIVERY

Microemulsion formulations offer the several benefits over conventional oral formulation including increased absorption, improved clinical potency, and decreased drug toxicity. Therefore, Micro emulsions have been reported to be ideal delivery of drugs such as steroids, hormones, diuretic and antibiotics.

TOPICAL DELIVERY

Topical administration of drugs can have advantages over other methods for several reasons, one of which is the avoidance of hepatic first-pass metabolism, salivary and degradation of the drug in stomach and related toxicity effects. Another is the direct delivery and targetability of the drug to affected areas of the skin or eyes. Now a day, there have been a number of studies in the area of drug penetration into the skin. They are able to incorporate both hydrophilic (5-flourouracil, apomorphine hydrochloride etc) and lipophilic drugs (estradiol, finasteride, ketoprofen etc) and enhance their permeation. Since formation of microemulsion formation requires high surfactant concentration, the skin irritation aspect must be considered especially when they are intended to be applied for a longer period.
OCULAR AND PULMONARY DELIVERY

For the treatment of eye diseases, drugs are essentially delivered topically. O/W microemulsions have been investigated for ocular administration, to dissolve poorly soluble drugs, to increase absorption and to attain prolong release profile.

OTHER PHARMACEUTICAL APPLICATIONS

1. Nasal delivery
2. Drug targeting
3. Cellular targeting
4. Brain targeting
5. Periodontal delivery
6. Tumor targeting

CONCLUSION

The role of microemulsion in providing novel solutions to overcome the problems of poor aqueous solubility of highly lipophilic drug compounds and provide high, more consistent and reproducible bioavailability. Till date, Micro emulsions have been shown to be able to protect labile drug, control drug release, increase drug solubility, increase bioavailability and reduce patient variability. Furthermore, it has proven possible to formulate preparations suitable for most routes of administration. There is still however a considerable amount of fundamental work characterizing the physico-chemical behavior of Micro emulsions that needs to be performed before they can live up to their potential as multipurpose drug delivery vehicles. Micro emulsions can also be used to achieve drug targeting however challenges remain, primarily because of the layers of barriers that these systems need to overcome to reach to the target. In today’s world Microemulsion is accepted as full of potential for novel drug delivery systems. Current research work is focused on the preparation of safe, efficient and more compatible microemulsion constituents which will further enhance the utility of these novel vehicles.
